# ABSTRACT

A fundamental question in software testing research is how to compare test suites, often as a means for comparing test-generation techniques that produce those test suites. Researchers frequently compare test suites by measuring their coverage. A coverage criterion C provides a set of test requirements and measures how many requirements a given suite satisfies. A suite that satisfies 100% of the (feasible) requirements is called C-adequate. Previous rigorous evaluations of coverage criteria mostly focused on such adequate test suites: given two criteria C and C', are C-adequate suites (on average) more effective than C'-adequate suites? However, in many realistic cases, producing adequate suites is impractical or even impossible.

This thesis presents the first extensive study that evaluates coverage criteria for the common case of non-adequate test suites: given two criteria C and C', which one is better to use to compare test suites? Namely, if suites  $T_1, T_2, \ldots, T_n$  have coverage values  $c_1, c_2, \ldots, c_n$  for C and  $c'_1, c'_2, \ldots, c'_n$  for C', is it better to compare suites based on  $c_1, c_2, \ldots, c_n$  or based on  $c'_1, c'_2, \ldots, c'_n$ ? This thesis evaluates a large set of plausible criteria, including basic criteria such as statement and branch coverage, as well as stronger criteria used in recent studies, including criteria based on program paths, equivalence classes of covered statements, and predicate states. The criteria are evaluated on a set of Java and C programs with both manually written and automatically generated test suites. The evaluation uses three correlation measures. Based on these experiments, two criteria perform best: branch coverage and an intra-procedural acyclic path coverage. We provide guidelines for testing researchers evaluating coverage criteria for research use.

To my family and friends.

### ACKNOWLEDGEMENTS

This thesis is the result of a two and a half year collaboration with Milos Gligoric and Darko Marinov from the University of Illinois; and Alex Groce, Chaoqiang "Super" Zhang, and Mohammad Amin Alipour from Oregon State University. We at Illinois are fortunate to have such dedicated and driven collaborators from Oregon.

I started working with my adviser, Darko Marinov, as a freshman undergraduate, when he was very willing to have me work in his group. I appreciate immensely the hands-on guidance and support Darko has given me over the past four years. Milos Gligoric and I started collaborating when he was a first-year Ph.D. student and I was a first-year undergraduate, and we have been great friends ever since. I am inspired by his ability to simultaneously work on several projects with several collaborators. In the future, I hope to mentor students with the same energy he mentored me.

I would also like to thank my co-adviser, Matthew Caesar, for sharing his enthusiasm for research. I wish I had more time to work with him. I am grateful to have groupmates and officemates Lamyaa Eloussi, Alex Gyori, Farah Hariri, Owolabi Legunsen, and August Shi for making my last semester at Illinois enjoyable. Last, I would like to thank Yu Lin for giving feedback on an early draft of this thesis.

### CHAPTER 1

# INTRODUCTION

Software testing helps developers to improve the quality of their code. Developers or test engineers run test suites and inspect failures to identify faults in the code. A fundamental task in software testing research is evaluating (and improving) test suites. For example, evaluating suites is central to the development of automated test-generation techniques whose goal is to generate high-quality suites.

To compare suites, researchers typically use real faults, seeded faults, and/or coverage criteria. For real faults, researchers measure how many faults (previously known or newly found) the suites find. However, collecting code with real faults and analyzing failures takes substantial effort. Thus, experiments often use a relatively small set of real faults, preventing rigorous statistical analysis of the results [7].

Researchers also use mutation testing [23,41,49] to seed a large number of artificial faults and measure the mutation score, i.e., how many mutants a suite kills. Several studies [5,6] show that the results obtained on mutants predict detection of real faults, i.e., suites that kill more mutants are *likely*, on average, to find more real faults. While mutation testing can provide a good basis for statistical analysis [7], it can also be prohibitively expensive to perform. Even a small program with only a few hundred lines of code may have thousands of mutants, and determining killed mutants may require running a test suite on each mutant.

Researchers therefore most often use *coverage* to compare suites. A traditional coverage criterion provides a finite set of test requirements for the code under test, and one measures how many requirements a given suite satisfies. For example, statement and branch coverage are well-known structural criteria [4]. A suite that satisfies 100% of the (feasible) requirements for a criterion C is called C-adequate. Measuring test coverage is almost always much cheaper than performing mutation testing; even if the criterion has a high runtime overhead,

it only requires running tests once per program, as opposed to once per mutant. Coverage criteria are widely used in testing research and practice, e.g., papers on automated testing techniques often report that one technique is better than another because it generates, say, "suites with 10% more branch coverage on average."

This thesis addresses the following question: What coverage criteria should researchers use to evaluate suites? Research comparing<sup>1</sup> coverage criteria dates back at least 20 years [27, 28, 46] but has largely focused on adequate test suites: given two criteria C and C', do C-adequate suites (on average) find more faults than C'-adequate suites? However, testing practice and research widely use non-adequate test suites because determining which test requirements are feasible is hard, generating suites for all feasible requirements is often impractical, and some recently used criteria [9, 15, 16, 35, 36, 58, 65, 69, 74] even have an infinite (or astronomically large) set of requirements.

To the best of our knowledge, there has been no *extensive* study comparing coverage criteria over *non-adequate suites* except for the recent ISSTA conference paper [31] co-authored by the author of this thesis. This thesis focuses on two critical questions:

- 1. Are any coverage criteria able to predict mutation scores for non-adequate suites, and thus suitable for use in evaluations?
- 2. Given two criteria C and C', is it better to use C or C' to compare test suites? Namely, if suites  $T_1, T_2, \ldots, T_n$  have coverage values  $c_1, c_2, \ldots, c_n$  for C and  $c'_1, c'_2, \ldots, c'_n$  for C', is it better to compare suites based on  $c_1, c_2, \ldots, c_n$  or based on  $c'_1, c'_2, \ldots, c'_n$ ?

To illustrate the key difference in comparisons with adequate and non-adequate suites, consider a comparison of statement coverage (SC) with branch coverage (BC). For adequate suites, it is well known that BC subsumes SC: a suite with 100% BC would have 100% SC and should, on average, be likely to find more faults than another suite with 100% SC but less than 100% BC. For non-adequate suites, however, the situation is less clear. For instance, suppose a suite  $T_1$  has 50% BC and 75% SC, and a suite  $T_2$  has 60% BC and 65% SC. (Our experiments show that up to 11% of test-suite pairs have such discordant values

<sup>&</sup>lt;sup>1</sup>Note that we use the term "comparison" to refer to both comparisons of suites and comparisons of coverage criteria, but the intended use should be clear from the context.

for BC and SC; more details are provided in Chapter 4.) Should we use BC and declare  $T_2$  better (60%>50%), or should we use SC and declare  $T_1$  better (75%>65%); is  $T_1$  or  $T_2$  more likely to kill more mutants? Substituting a variety of criteria for branch and statement coverage, this scenario describes a common occurrence in evaluation of testing techniques.

The major contribution of this thesis is an evaluation of multiple criteria, both traditional (statement and branch) and recently used (based on program paths, equivalence classes of covered statements, and predicate states). We evaluated criteria on a large set of Java and C programs with both manually written and automatically generated tests. We measured the effectiveness of criteria (using three statistical correlation coefficients) in terms of how well they predicted the mutation scores of suites (and thus, arguably, the real-fault detection of suites [5,6]). We designed our experiments to have a direct application to the evaluation of suites (and thus testing techniques) in testing research, and propose that our experimental approach would easily extend to other criteria, programs, and subjects. A minor contribution of this thesis is the first implementation and evaluation of Ball's predicate-complete test coverage criterion (PCT) [9,10]. In Chapter 3, we describe all implementation challenges we faced in both Java and C.

Our results show that a variety of criteria are able to effectively predict mutation scores. This provides support for previous research studies that used these criteria to compare test suites. Moreover, for future studies, we propose two guidelines for researchers using coverage criteria to evaluate suites. First, our results show that branch coverage performs as well as or better than all other criteria studied, in terms of ability to predict mutation scores, and has a very low measurement overhead and implementation complexity. However, in some settings, branch coverage provides values that do not distinguish between test suites. Second, if researchers want a stronger criterion that can distinguish more test suites, but comes at the price of increased measurement overhead and implementation complexity, our results show that an acyclic intra-procedural variation of path coverage is about as effective as branch coverage. Our results also demonstrate that for non-adequate suites, criteria that are stronger (in terms of subsumption for adequate suites) do not necessarily have better ability to predict mutation scores. Additionally, as a guideline for future studies evaluating the effectiveness of criteria themselves, we suggest that results be based on a large set of

suites generated by as many techniques as feasible for as many subjects as feasible, and that multiple correlations be measured to ensure that the results do not depend on a particular choice of correlation. All tools, source code, and experimental subjects, along with more results, are publicly available at: http://mir.cs.illinois.edu/coco/.

The contributions of this work include:

- The first extensive study on comparing how coverage criteria predict mutation score for non-adequate suites.
- The first implementation of the Predicate-Complete Test (PCT) coverage criterion.
- The first evaluation of the Dynamic Basic Block (DBB) measurement as a coverage criterion. DBB was previously proposed for fault localization [12].
- Some guidelines for using coverage criteria to compare suites in testing research.
- One guideline for performing future studies on comparing coverage criteria.

### CHAPTER 2

### COVERAGE CRITERIA

Our comparison of criteria includes SC and BC, which are standard in practice. Our evaluation also includes a set of criteria based on program paths, equivalence classes of covered statements, and predicate states, which we define and illustrate in this section using a simple Java data structure. (Note that our implementations support larger programs in both Java and C.) Figure 2.1.a shows the relevant part of a class implementing the binomial heap data structure [20,69] that supports fast union operation. The figure shows only the part of the BinomialHeap class relevant for our discussion. Each BinomialHeap object has a pointer to the root of the heap (nodes) and the number of nodes in the heap (size). Every node keeps a value (key) and pointers to its parent, sibling, and child. The decreaseKey method decreases the value of a node, which may affect the heap invariant that each parent should not have a higher value than its children, so the value is propagated to ancestors until the appropriate position is found.

# 2.1 Dynamic Basic Block Coverage (DBB)

We first describe Dynamic Basic Block (DBB) coverage, which may be unfamiliar to most readers outside the fault-localization community. Baudry et al. [12] proposed the notion of a dynamic basic block<sup>1</sup> to measure a test suite's effectiveness for fault localization. Suppose we are given a program and execute a number of tests on the program. Consider a partition of the program statements into equivalence classes, where two statements belong to the same equivalence class if and only if they are covered by the same set of tests. Each equivalence class is called a *dynamic basic block* (DBB). The Baudry et al. study [12] showed that the

<sup>&</sup>lt;sup>1</sup>Not to be confused with dynamic basic blocks as used in computer architecture or compilers [59].

```
1 // public class BinomialHeap { ...
                                                  void decreaseKey(int oldKey, int newKey) {
2 static class Node {
                                                    try {
                                                       Coverage.beginMethod(0);
    int key;
    Node parent;
                                                       Node tmp = nodes.findNodeWithKey(oldKey);
                                                       if (tmp = null) {
6 }
                                                         Coverage.cover (
7 Node nodes;
                                                           1,p$10(nodes),p$20(tmp));
8 int size;
10 void decreaseKey(int oldKey, int newKey) {
                                                       Coverage.cover(2,p$10(nodes),p$20(tmp));
    Node tmp = nodes.findNodeWithKey(oldKey);
    if (tmp == null) return;
                                                       tmp.key = newKey;
12
    tmp.key = newKey;
                                                       Node tmpParent = tmp.parent;
13
    Node tmpParent = tmp.parent;
                                                       while ((tmpParent != null)
14
    while ((tmpParent != null)
                                                             && (tmp.key < tmpParent.key)) {
15
           && (tmp.key < tmpParent.key)) {
                                                         Coverage.cover (3, p\$10 (nodes), p\$20 (tmp),
16
      int z = tmp.key;
                                                          p$21(tmpParent),p$49(tmp,tmpParent));
17
18
      tmp.key = tmpParent.key;
                                                         int z = tmp.key;
      tmpParent.key = z;
19
                                                         tmp.key = tmpParent.key;
      tmp = tmpParent;
                                                         tmpParent.key = z;
20
      tmpParent = tmpParent.parent;
                                                         tmp = tmpParent;
21
                                                         tmpParent = tmpParent.parent;
22
23 }
                                                       Coverage.cover (4,p\$10 (nodes),p\$20 (tmp),
24
25
                                                         p$21(tmpParent), p$49(tmp, tmpParent));
                                                      catch (Exception e) {
26
27
                                                       Coverage . endMethod ();
28
29
                                                  }
                                                                         (b)
  1 // tmp.key < tmpParent.key
  2 boolean p$49 (Node tmp, Node tmpParent) {
                                                          nodes
       if (PCT.testAndSetInPredicate())
         return false;
       if (tmpParent == null) return false;
  6
       if (tmp == null) return false;
       return tmp.key < tmpParent.key
     } catch (Exception _) { return false;
      finally { PCT.resetInPredicate(); }
 10
 11 }
                                                                         (d)
```

Figure 2.1: BinomialHeap as running example

larger the number of DBBs a test suite has, the more effective the test suite is for spectrum-based fault localization. The underlying rationale is that having few DBBs equates to a suite having little ability to distinguish statements with respect to their causal impact on fault behavior. We use the number of DBBs as a test coverage metric instead, on the grounds that these equivalence classes show distinct program behaviors that are not explored. Every DBB that can be broken by some test not in a suite (where statements are always executed together in that suite, but this is not required for another suite) also indicates a missing whole program path for that suite. For example, consider the instance of BinomialHeap

shown in Figure 2.1.d.

Assuming that there are two tests available for the decreaseKey method — (9, 8) and (9, 2) — the total number of DBBs is two. The first DBB includes all the statements before the while loop, i.e., lines between 10 and 16 (Figure 2.1.a); these lines are covered by both tests. The second DBB includes all the statements in the body of the while loop, i.e., lines between 17 and 22; these lines are covered only by the second test. We say that this test suite has DBB coverage of 2. In general, a program with s statements having a test suite of t tests can partition the program into up to  $\min(s, 2^t)$  DBBs. DBB is obviously not useful for suites that consist of only a single very large test, and has a limited value to distinguish suites that have a small number of tests.

# 2.2 Intra-Method Path Coverages (IMP and AIMP)

We next describe two forms of path-based coverage used in our evaluation. Whole-program path coverage was proposed over 20 years ago [52] to measure how many different paths tests execute from the beginning to the end of a program. Even for loop-free programs, whole program paths result in a number of test requirements exponential in the number of branches in a program, so more recent work [16, 34, 36, 74] used more scalable *intra-method paths (IMP)*, where each path is for a single method execution only (similar to Godefroid's notion of *compositional* path coverage [32]). An intra-method path starts at the beginning of a method, includes the IDs of the executed basic blocks<sup>2</sup>, does not include nested method invocations, and ends when the execution returns from the method. IMP subsumes BC (and thus SC) but faces the problem that loops introduce an unbounded number of test requirements.

Our second variant of path coverage, acyclic intra-method paths (AIMP), retains subsumption of BC but bounds the total number of requirements by considering only acyclic paths in intra-method control-flow graphs [11]. The number of AIMP paths is therefore bounded by  $m \cdot 2^k$  where m is the number of methods in a program and k is the maximum number

<sup>&</sup>lt;sup>2</sup>These are the standard basic blocks, not dynamic basic blocks from DBB. When we want to refer to DBBs, we explicitly use "dynamic".

of branches in a single method. The paths to be covered have no repeated IDs, i.e., AIMP modifies IMP such that a repeated basic block ID ends the current path and starts a new path<sup>3</sup>. Ball and Larus present an efficient approach to compute AIMP coverage [11].

Figure 2.1.b shows an instrumented version of decreaseKey that can be used to collect IMP and AIMP coverages. (The p\$ methods will be discussed in the next section.) Coverage.beginMethod and Coverage.endMethod are invoked at the beginning and end of the method, respectively, and they are used to begin and end a path. Coverage.cover is invoked at each basic block and is used to collect the block IDs in a path. In addition, for AIMP, the Coverage.cover method may end the current path and start a new path if the block ID is repeated on the current path. For example, consider the instance of BinomialHeap shown in Figure 2.1.d.

Invoking decreaseKey on that heap with arguments (9, 8) executes the IMP  $0 \to 2 \to 4$  and covers the same path for AIMP. (Note that 0, 2, and 4 refer to IDs of basic blocks). Invoking decreaseKey on that heap with (9, 2) instead executes the IMP  $0 \to 2 \to 3 \to 3 \to 4$  but covers two paths for AIMP:  $0 \to 2 \to 3$  and  $3 \to 4$ . Note that IMP and AIMP collect paths for every method run, e.g., each invocation of decreaseKey calls findNodeWithKey (which may invoke other methods), so for each invocation, IMP has one path (and AIMP at least one path) for both methods.

#### 2.3 Predicate-Complete Test Coverage (PCT)

Predicate-complete test coverage (PCT) [9,10] was introduced by Ball as a finite-state alternative to path coverage, inspired by predicate abstraction in model checking [8]. Like path coverage, PCT subsumes both BC and SC, but unlike some versions of path coverage, PCT does not face the problem that loops introduce an unbounded number of test requirements. PCT is incomparable to (i.e., neither subsumes nor is subsumed by) path coverages such as IMP and AIMP, even for loop-free programs. Several research studies [35, 36, 58, 65, 69] compared test suites using PCT, but with manually selected predicates for measuring PCT;

<sup>&</sup>lt;sup>3</sup>Our AIMP uses the notion of simple path common in graph theory, where no vertex is repeated, rather than definition of prime path found in some testing literature [4].

we refer to this version as  $PCT_{MS}$ .

PCT defines coverage using Boolean predicates extracted from the program source, in particular from branch conditions, implicit run-time checks, and program assertions. These predicates are evaluated at many program points, e.g., at all statements or all starts of basic blocks, potentially far from where the predicates appear in the program source. In fact, evaluating predicates both near and far from where they appear is what makes PCT even stronger than MC/DC or other related criteria sometimes called "predicate coverage" [4] that evaluate predicates only near where they appear. The test requirements for PCT are to cover all (feasible) combinations of predicate values at all the points. In the limit, for n predicates at p points, there are  $p \cdot 2^n$  combinations (many often infeasible, and not every point has all n predicates). The PCT coverage for a test suite is measured as the number of combinations of predicate values obtained during the execution of the test suite.

We next illustrate PCT using the BinomialHeap example. The first step is to extract a set of Boolean predicates from the code under test. Our example code has two conditional statements at lines 12 and 15 (Figure 2.1.a), which lead to three predicates: tmp == null, tmpParent != null, and tmp.key < tmpParent.key. Note that we take as a predicate each atomic condition rather than the complex expression. The implicit run-time checks in our example guard against dereferencing null: nodes != null, tmp != null, and tmpParent != null. Note that the same predicate may be extracted several times, so syntactically identical duplicates are removed (Section 3). A key goal for PCT is to extract all predicates, as otherwise PCT may not subsume BC or MC/DC.

The second step is to insert evaluation of predicates at all appropriate program points. Our tool first generates a method for evaluating each predicate and then inserts calls to these methods. Note that one cannot simply evaluate the predicate as it could lead to problems, e.g., raise an exception if certain variables are null. The method for each predicate performs the necessary checks. Figure 2.1.c shows the method for the predicate tmp.key < tmpParent.key. The methods Coverage.testAndSetInPredicate and Coverage.resetInPredicate guard against infinite recursion. The catch clause handles exceptions in predicate evaluations.

For program points, our PCT tools for Java and C allow instrumenting all statements,

 $PCT_{ST}$ , or all beginnings of basic blocks,  $PCT_{BB}$ . Figure 2.1.b shows an example instrumentation at the basic-block level. Each Coverage.cover call informs the tool that a certain program point (identified with an integer ID) is being executed with a specific combination of predicate values. Note that predicates cannot be evaluated at points where their variables are not in scope, e.g., the predicates for tmpParent cannot be evaluated before line 13. Our tools insert evaluation for all predicates that can be evaluated. Some predicates can be evaluated far from where they are extracted, e.g., nodes != null is evaluated on line 16 (Figure 2.1.b), although it is extracted based on line 4 (Figure 2.1.b). Some predicates (on instance fields, rather than on method local variables) can even be extracted in one method and evaluated in another method.

While PCT<sub>BB</sub> maintains the key subsumption properties of PCT over BC, it is only an approximation of PCT<sub>ST</sub> because statements within a block can change predicate values. The example shows that this is not unusual: tmp.key, tmpParent.key, and tmp are all modified inside the block beginning at line 15 (Figure 2.1.b) in ways that may introduce combinations of predicate values that will never be seen at basic block entries.

# CHAPTER 3

### PCT IMPLEMENTATION

As stated previously, one of our contributions is the first implementation of Ball's PCT [9], and therefore we are the first to encounter a number of unique challenges related to this coverage criterion. We find it important to document our experiences related to these unique challenges. Specifically, we find that the design of a programming language may impose fundamental problems for correct and efficient implementation of PCT, by making certain information unavailable at runtime. In the following sections, we first discuss the implementation for both Java and C<sup>1</sup>, challenges that are both unique and shared by these languages, and how we addressed these challenges.

#### 3.1 Java Implementation

We implemented our tool for measuring PCT for Java as an Eclipse headless plugin [25] that performs source-to-source instrumentation. The tool can instrument the code under test for measuring PCT at each statement or each basic block.

#### 3.1.1 Extracted Predicates

According to the original source on PCT [9], all atomic predicates should be extracted from conditional statements, implicit run-time checks, and assertions. For complex conditionals or assertions, e.g., A | | (B && C), each of A, B, and C must be treated as a separate predicate (otherwise, PCT could not subsume multiple condition coverage). However, the original source [9] gives no specific instructions on which run-time checks to consider. To limit the

<sup>&</sup>lt;sup>1</sup>Note that the author did not develop the tool for C. This tool was developed by collaborators [31].

cost of instrumentation, our tool considers only two types of run-time checks for creating predicates: null dereference and index out of bound. It creates one predicate for each field access (e.g., predicate obj != null for obj.f) and method invocation (e.g., predicate obj != null for obj.m()), and two predicates for each array element access (e.g., predicates arr != null and 0 <= i && i < arr.length for arr[i]).

#### 3.1.2 Minimizing the Set of Predicates

We maintain predicates as a set and do not instrument multiple occurrences of the same predicate multiple times, for efficiency reasons. We are limited in our ability to detect semantically, rather than syntactically, equivalent predicates (the problem is not decidable); even when semantically duplicate predicates appear in instrumentation, they do not change the total number of covered location-predicate values (redundant bits in a bit vector do not change the bit vector equality).

# 3.2 C Implementation

We implemented our tool for measuring PCT for C as a source-to-source transformation using the CIL framework [55]. Like the Java version, the C version allows us to choose instrumenting each basic block or each statement.

The challenges in extracting predicates in C are somewhat different than in Java. C is arguably a simpler language than Java, e.g., lacking inheritance or exceptions and having simpler scoping rules. Unfortunately, attempting to instrument real-world C programs for PCT faces challenges rooted in the C language itself.

The fundamental problem is that C is an unsafe language. In Java, it is easy to perform runtime checks to avoid invalid memory accesses: the length of an array can be queried, and if a reference is not NULL, it is valid. In C, however, arrays do not carry length information and pointers can be non-NULL yet point to deallocated or remote memory—a C pointer is simply an arbitrary memory address. The only way to safely capture values for most predicates involving pointers or arrays in C would be to further instrument the

program to track array lengths and check pointers for validity. However, the overhead of such instrumentation is unfortunately high for many C programs — an additional 2-5 slowdown over predicate instrumentation in runtime and 2-10 times additional overhead in memory usage for an efficient tool such as Purify, and possibly more for instrumentation that can work with our predicate instrumentation [2]. Therefore, in our tool we have chosen not to instrument predicates using pointers or array referencing.

The core instrumentation is quite simple: after transforming the input code to the CIL's canonical form, a CIL visitor first traverses the program collecting predicates (and their scopes), and then another visitor inserts function calls to capture values at each block or statement.

#### 3.3 Challenges

During the implementation of our tools we discovered several technical challenges unique to measuring PCT coverage. We discuss these challenges, marking each with the language— $^{J}$  for Java,  $^{C}$  for C, and  $^{JC}$  for both—in which the challenge is identified.

#### 3.3.1 Side Effects $^{JC}$

Simply extracting all expressions that appear in conditional statements and evaluating these exact syntactic expressions at certain program points can lead to incorrect instrumentation because a conditional expression may contain side effects, such as assignments, prefix/postfix operators, or invocations of methods/functions that modify the program state. Because of side effects, the state of the instrumented program at some point in the execution may not match the state of the original program at the corresponding point in the original execution. To identify side effects, we implemented a (simple) purity analysis [61,68] using WALA [73] for Java. The analysis checks each extracted predicate and does not instrument elsewhere for those that are not side-effect free. In C, CIL removes the problem of side effects by using temporary variables to make all conditionals side-effect free. This means that in C, we often instrument a predicate for a temporary variable only assigned once. This is not clearly worse

than simply not instrumenting the predicate: it captures some additional states, without adding any spurious states since the temporary value is local in scope.

#### 3.3.2 Recursive Predicate Invocation $^{JC}$

Each predicate can contain an arbitrary expression, as long as the expression does not have side effects. Therefore, a predicate may contain an invocation of a method that invoked the predicate, which would lead to infinite recursion. To prevent this, the instrumentation inserts special method calls at the beginning and end of each predicate. Recall Figure 2.1.b. The method Coverage.testAndSetInPredicate checks a Boolean flag that indicates whether a predicate evaluation has started. If no evaluation has started, it sets the Boolean flag and starts the predicate evaluation. If the flag was already set, the predicate would not be evaluated. The method Coverage.resetInPredicate simply resets the Boolean flag to mark the end of the evaluation.

#### 3.3.3 Field/Element Access or Method Invocation $^{JC}$

A predicate can contain arbitrary (side-effect free) expressions including field accesses, method invocations, or array-element accesses. Since a predicate can be evaluated at any program point where the variables used in the predicate are visible, some of these expressions could lead to null pointer dereference or index out of bounds exceptions (in Java) or other problems (in C). For C, our tool does not use such predicates. For Java, our tool adds checks to the predicates, specifically a null check for each field access and method invocation and both a null check and bound check for each array element access. If all checks are satisfied, the predicate is evaluated, otherwise the evaluation of the predicate is ignored. In the example in Figure 2.1.c, there are checks for tmp != null and tmpParent != null.

#### 3.3.4 Checked Exceptions $^{J}$

A Java predicate can in general contain an invocation of a method that declares some checked exceptions (e.g., IOException). Such exceptions have to be either propagated to

a caller (by specifying the types of the exceptions in the throws clause) or caught. We did not want to simply ignore such predicates (especially since they can be important for bugs related to exceptional control flow [29]). Instead, our implementation adds code to catch the exception(s) and ignores the evaluation of the predicate if an exception is caught. Figure 2.1.b shows such a catch block, although it is not strictly required for that example predicate. In practice, only a small percentage of predicates requires catching exceptions, because our purity analysis already filters out most of the methods that may throw an exception.

#### 3.3.5 Inner/Anonymous Classes and Class Hierarchy<sup>J</sup>

Our current implementation does not instantiate certain predicates that could be in theory instantiated across class boundaries but do not occur often in practice. First, inner/anonymous classes in Java can access predicates from the outer classes. However, an additional check would be needed to ensure that a predicate from an outer class can be instantiated in an inner class: all local variables needed as the predicate arguments must be declared final. Similarly, some predicates extracted from inner classes could be instantiated in the outer classes if all the variables used in the predicate are declared in the outer classes. Second, predicates that are extracted from a class and reference its instance fields are in principle visible in all subclasses (that do not shadow these fields). The reason to ignore these predicates is additional implementation burden required to track relation between classes and to keep predicates across instrumenting multiple classes.

#### 3.3.6 Method Size $\operatorname{Limit}^{J}$

In a few cases, our instrumentation produced code that was so large that it was rejected by some Java compilers. Namely, there were many predicates and points in the instrumented code, and some of the instrumented methods exceeded the 64KB limit set by the Java classfile specification [71]. One approach to reduce the size would be to (randomly) select only some predicates and/or program points for PCT where the predicates should be instantiated.

However, a good way to select predicates and/or points is not known as of now. Thus, we decided to ignore all predicates and points that lead to methods that exceed the limit.

# CHAPTER 4

# EXPERIMENTAL METHODOLOGY

To compare coverage criteria, we examine first and foremost how well the coverage values predict test suite quality in terms of mutation scores. We additionally consider the cost of measuring coverage. We compare two traditional criteria (SC and BC) and three sets of recently used criteria based on equivalence classes of covered statements (DBB), program paths (IMP and AIMP), and predicate states (various PCT<sub>MS</sub>, PCT<sub>BB</sub>, and PCT<sub>ST</sub>).

Testing literature does not have one agreed upon methodology for comparing test coverage criteria, so we motivate and describe the methodology we use. Coverage values are used to evaluate suites, typically as predictors for finding real faults. Intuitively, if a good criterion deems one suite better than another suite, then we expect the better suite to find, on average, more faults. However, performing large controlled experiments with real faults is hard due to the difficulty of collecting many suitable faulty programs, and statistical validity is difficult to attain with the typically small number of faults in each program. For these reasons, while older studies on comparing coverage criteria used (a small number of) real faults [27,28,46], more recent studies use (a large number of) systematically seeded mutants [6,13,53].

Specifically we examine the ability of coverage values to predict (the relative ordering or absolute values of) mutation scores. To visualize this concept, Figure 4.1 shows eight plots (for eight coverage criteria) that relate coverage values and mutation scores for BinomialHeap. Each point represents one of 300 suites (selected as explained in Section 4.2). The X-axis shows coverage, normalized between 0.0 and 1.0, and the Y-axis shows mutation score<sup>1</sup>. It is clear in all six plots that if a suite A has a higher coverage than a suite B, then the suite A also likely has a higher mutation score than the suite B. The purpose of our statistical

<sup>&</sup>lt;sup>1</sup>The mutation score is not normalized, but dividing by a constant never changes values for our three correlations.

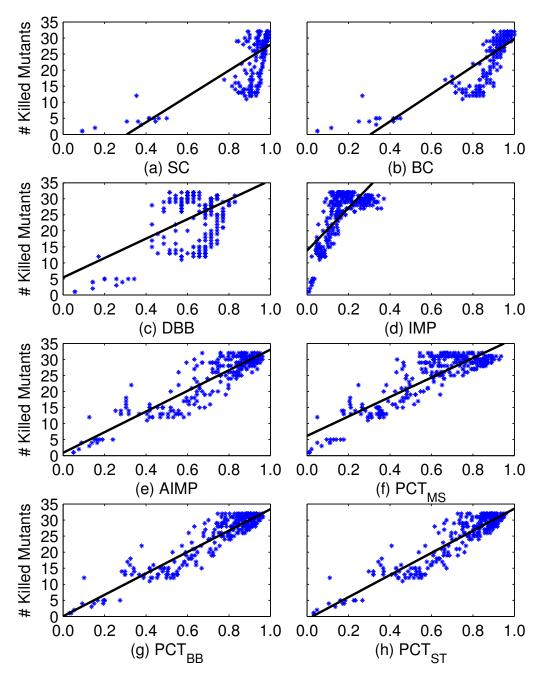

Figure 4.1: Coverage criteria values and mutation scores correlation for BinomialHeap

evaluation is to quantify the degree to which this relationship holds for each criterion, and thus to compare criteria. We apply three different standard statistical tools: Kendall's  $\tau_b$  rank correlation, Spearman's  $\rho$  rank correlation, and the  $R^2$  coefficient of determination for linear regression, discussed in detail in Section 4.4. Intuitively, Kendall's  $\tau_b$  and Spearman's

Table 4.2: Subject programs used in the evaluation (coverage statistics)

#### 4.1 Experimental Subjects

Programs: Table 4.1 summarizes the programs used in our experiments, showing the name and number of NBNC (non-blank, non-comment) lines of code (measured by CLOC [18]) for each program. We used a total of 26 programs, 15 Java programs and 11 C programs. All Java programs but two are implementations of data structures that have been used in numerous previous studies, primarily on comparing different testing techniques [30, 35, 36, 64,65,69]. JFreeChart [48] is an open-source library for both interactive and non-interactive manipulation of charts. JodaTime [50] is an open-source library for manipulating date and time. For C, seven programs are from the Siemens suite from the SIR repository [24, 46], Space [24,72] is a bigger program from the same repository, SglibRbtree [70] is the red-black tree implementation from the Sglib library, YAFFS2 [78] is a widely used open-source flash file system for embedded devices (the default image format for older versions of Android), and SQLite [67] is a widely deployed database engine.

Tests: Table 4.1 also shows the total number of tests in the test pools from which various test suites are selected. For Java data structures, we use test pools automatically generated in previous studies [35,36,65] using three test-generation techniques: random (Random), shape abstraction (ShapeAbs) [69], and adaptation-based programming (ABP) [35,36]. Table 4.1 shows the total number of tests generated by all three techniques. For JFreeChart and JodaTime, we use the large, publicly available pool of manually written JUnit tests. For C programs, we use the Siemens/SIR test pools for the programs from SIR. For SglibRbtree and YAFFS2, we generated random tests (feedback-directed [37] for YAFFS2). For SQLite we use manually written tests available from the SQLite repository [67].

Mutants: Table 4.1 also tabulates for each program the number of mutants created and the total number of mutants killed by the entire test pool (while different suites selected from the pool kill different number of mutants). The percentage of killed mutants is low because we mutated all the methods in the code but automatically generated tests execute only some core methods for the smaller subjects [65]. Low absolute mutation scores are suitable for our purpose of examining non-adequate suites, the typical case for suites for large programs. Non-adequate suites will seldom attain extremely high mutation scores. Additionally, we did

not investigate which mutants are equivalent, as this does not affect our analysis (because compensating for equivalent mutants is equivalent to dividing mutation score by a constant, which does not affect  $\tau_b$ ,  $\rho$ , or  $R^2$ ).

For Java programs, we used Javalanche [62] to create mutants. Because the number of mutants may be lower than one would expect, it should be noted that Javalanche uses selective mutation [56] to reduce the cost of mutation testing. Selective mutation applies only a subset of mutation operators that are empirically shown to approximate the results that would be achieved if all operators were used. In particular, Javalanche uses only the following operators: replace numerical constants, negate jump condition, replace arithmetic operator, replace method calls, and remove method calls. Still, Javalanche created over 45K and 24K mutants for JFreeChart and JodaTime, respectively.

For C programs, we created mutants using the tool implemented by Andrews et al. [5], which produces mutants based on a set of operators selected through an empirical study on selective mutation [54]. Specifically, the tool uses the following operators: replace constants; delete statements; negate decisions in conditional statements; and replace a relational, arithmetic, logical, bit-wise logical, increment/decrement, or arithmetic-assignment operator by another operator from the same class.

Statement and Branch Coverage Information: The SC and BC columns in Table 4.2 provide information for statement and branch coverage, respectively: "static" shows the number of branches in the code, and "exe" shows the number of branches executed by at least one test.

DBB Information: Table 4.2 also provides DBB-specific information, i.e., the total number of DBBs obtained by using a single test suite consisting of the entire test pool summarized in Table 4.1. Note that the total number of DBBs differs when we select different test suites from the test pool. For SQLite, DBBs are not meaningful as "suites" consist of a single lengthy execution sequence with no breakdown into separate tests.

**IMP and AIMP Information:** Table 4.2 also provides the total number of paths executed by the entire test pool.

**PCT Information:** Table 4.2 finally provides PCT-specific information, i.e., the total number of predicates used in the instrumentation, the number of program points at which

these predicates are inserted, and the number of executed states (i.e., encountered states during the execution) by the entire test pool. MS ("Manually Selected") denotes a set of predicates and points that were first manually selected for four data structures by Visser et al. [69] and then similarly selected for the remaining structures by Sharma et al. [65]. These programs, with manually selected predicates for PCT coverage, are publicly available [22]. BB ("Basic Blocks") and ST ("Statements") denote the results of automatic instrumentation by our PCT coverage tools. Recall that our tools select (almost) all predicates from the code and insert each predicate at (almost) all program points where the variables from the predicate are in scope.

#### 4.2 Test Suites

We used two approaches for selecting test suites, to see if results are robust in the face of different suite compositions. The bounds in our approaches (e.g., 100 test suites) were chosen before experimentation, to limit computation time while providing sufficiently many samples for statistical analysis, or were chosen to match previous papers.

Coverage-varied Selection: For each program, to ensure that the selected test suites are of varying coverage and size, we created suites by first uniformly selecting a coverage level between 1% and 100% and then randomly selecting tests from the test pool until they reached the selected level of  $PCT_{BB}$  coverage. We picked  $PCT_{BB}$  as one strong criterion but could have used any other criterion. For the Java data structures we selected 100 suites from the pool for each of the three test-generation techniques (Random, ShapeAbs, and ABP), giving a total of 300 test suites. For JFreeChart and JodaTime we used 100 test suites created following the same steps. Similarly, for all C programs except SQLite we used 300 suites. For SQLite each "test" in the pool is essentially a large suite of tests that must run together, so we treated each of the 592 "tests" as a suite.

Size-varied Selection: We also followed another suite selection approach, used in previous studies of coverage criteria [43, 53]. For each program, we created 100 random suites for each size (number of tests) between 1 and 50, which gives 5,000 suites per program, but with less varied coverage than Coverage-varied Selection. Also, this approach creates many

suites that are near adequate in at least one criterion and does not include suites based on different test generation techniques, which most closely reflect the intended purposes of our evaluation. SQLite was handled as for the Coverage-varied Selection.

#### 4.3 Metrics

We collected several metrics for the selected test suites.

Coverage Criteria: For each suite, we measured several coverage values (for both Java and C): SC, BC, DBB, IMP, AIMP, PCT<sub>MS</sub> (except for JFreeChart, JodaTime, and all C programs), PCT<sub>BB</sub>, PCT<sub>ST</sub>, and mutation score.

Runtime Overhead: We separately ran each coverage measurement so that we could measure the runtime overhead. We performed all Java experiments on a machine with a 4-core Intel Core i7 2.70GHz processor and 4GB RAM, running Linux version 3.2.0 and Java OpenJDK 64-Bit Server VM, version 1.7.0\_04. We performed all C experiments on a machine with a 4-core Intel Xeon E5400 2.83GHz processor and 4GB RAM, running Linux version 2.6.32.

#### 4.4 Correlation Analysis

To evaluate the relationship between coverages and mutation scores, we computed three correlation measures.

Kendall's  $\tau_b$ : One core question of this paper is whether (and which) coverage criteria can be used to effectively predict the rank order of suites' mutation scores. This is the primary use of coverage in recent studies; authors have tended to focus on claiming that some testing technique is "better", and relatively small differences in coverage values have been used to justify a claim of "better" [36,69]. The most robust and usefully interpreted statistical measure for this question is Kendall's  $\tau$  rank correlation coefficient [17,51].

Consider the coverage and mutation score data as a set of pairs (C, M), where C is the coverage value for a suite and M is the mutation score for that suite. Two pairs  $(C_1, M_1)$  and  $(C_2, M_2)$  are called *concordant* if the ordering of  $C_1$  and  $C_2$  matches the ordering of

 $M_1$  and  $M_2$ , i.e.,  $C_1 < C_2$  and  $M_1 < M_2$  or  $C_1 > C_2$  and  $M_1 > M_2$ . The pairs are called discordant if  $C_1 < C_2$  and  $M_1 > M_2$  or  $C_1 > C_2$  and  $M_1 < M_2$ . Kendall's  $\tau$  is the ratio of the difference between the number of concordant and discordant pairs and the total number of pairs. Kendall's original  $\tau$  does not handle ties well, and thus was not suitable for our study, where several criteria can have many ties among suites for some subjects.

To illustrate concordant and discordant pairs, consider three test suites  $T_1, T_2, T_3$  that have respective coverage values 0.3, 0.4, 0.5 and mutation scores 0.7, 0.6, 0.8. There are 2 concordant pairs —  $(T_1, T_3), (T_2, T_3)$  — where higher/lower coverage values have higher/lower mutation scores, and one discordant pair —  $(T_1, T_2)$ .

Kendall's  $\tau_b$ , used in our study, is a standard adaptation that adjusts for ties [21]. Using a non-parametric rank correlation allows us to avoid the difficult question of whether the relationship between any criterion and mutation score is linear;  $\tau_b$  does not make any assumption about the underlying functional relationships. A final attractive feature of  $\tau_b$  is that in the absence of ties, the value can be intuitively interpreted:  $0.5 + |\frac{\tau}{2}|$  is the probability of correctly predicting the ordering of mutation scores using the ordering of coverage values [21]. Despite these desirable features of  $\tau_b$ , our study is among the first to use  $\tau_b$  in comparison of multiple coverage criteria. (A few studies [53,76,77] only mention  $\tau$  or use it for other purposes.) Values for  $\tau_b$  range from -1.0 (which would indicate that the coverage values are always opposite of the mutation score) to 1.0 (which would indicate a perfect predictive power for a criterion); a  $\tau_b$  of 0.0 indicates there is no relationship between the rank ordering by the criterion and rank ordering by mutation score.

Spearman's  $\rho$ : A statistic similar to  $\tau$  or  $\tau_b$  is Spearman's  $\rho$  [66]; it is also a rank correlation coefficient. The primary arguments for  $\rho$  are tradition and ease of calculation. Also, Spearman's  $\rho$  handles ties by averaging the ranks. In many cases,  $\rho$  and  $\tau/\tau_b$  are very similar in value. Intuitively, we use  $\rho$  to measure the degree to which the coverage values and mutation scores are monotonic. When  $\rho$  is positive, it implies that coverage value tends to increase when mutation score increases, and when  $\rho$  is negative, it implies that coverage value tends to decrease when mutation score decreases. A  $\rho$  correlation coefficient of 1.0 indicates a perfect increasing monotone fit, and a coefficient of -1.0 indicates a perfect decreasing monotone fit. (Only a few previous studies of coverage criteria [54, 76] briefly

mention Spearman's  $\rho$ .)

 $\mathbf{R^2}$ : We also formed linear regression models for each criterion and obtained the  $R^2$  coefficient of determination for the fits of those models to our data. It is well known that mutation scores do not depend linearly on coverage values [6, 13, 43, 53], but  $R^2$  still gives an indication of correlation. Intuitively, it attempts to answer the question: if one suite has X% higher coverage value than another suite, does it have a  $c \cdot X\%$  higher mutation score? More precisely, it shows how well a linear model fits the actual data points, with 1.0 indicating a perfect fit and 0.0 indicating there is no relationship between the coverage and mutation score. Figure 4.1 shows lines that best fit the observed data.

# CHAPTER 5

# EXPERIMENTAL RESULTS

# 5.1 Kendall's $\tau_b$ Rank Correlation

Tables 5.1 and 5.2 show Kendall's  $\tau_b$  correlation values for all subjects and all criteria we examined, for Coverage-varied Selection and Size-varied Selection, respectively. Each section highlights the best (darker/green) and worst (lighter/red) values. Values for PCT<sub>MS</sub> are missing where manual selection of predicates was not used, and values for SQLite are repeated for both approaches. The first key observation is that most criteria had  $\tau_b$  values over 0.5, often over 0.7, for most subjects. Using any of the criteria studied would correctly predict mutation score rankings for a large fraction of all suite pairs. Based on the standard Guilford scale [39], we would say that the mean values often showed high (> 0.7) or nearly high (> 0.6) correlation, and almost all correlations were at least moderate (> 0.4). All values below 0.4, for criteria other than DBB, IMP and PCT<sub>MS</sub>, came from just 4 simple Java data-structure classes. Given DBB's occasionally negative correlations, it is not clear that DBB is a useful criteria for suite evaluation for any purpose but fault localization, although even DBB often correlated very well.

The second key observation is that the absolute values and relative effectiveness of criteria vary with subject and test-suite selection approach, in a few cases by a wide range. However, considering all subjects and both approaches, it is clear that BC performs very well, and AIMP seems to perform best of the non-branch criteria (although PCT<sub>BB</sub> and PCT<sub>ST</sub> have slightly higher means for Coverage-varied Selection). For large subjects, coverage and mutation score ties were rare enough (more details in Section 5.7) that the values in the tables can be reasonably interpreted as indicating these criteria predict mutation score rank successfully 80% or more of the time. We additionally note that our results support, to a

considerable extent, previous studies that used newer path and predicate criteria to evaluate test suites/techniques [9,15,16,35,36,58,65,69,74]: while PCT criteria were not our best, the PCT<sub>MS</sub> with manually selected predicates performed well, and PCT performed better than IMP, which was used in fewer studies. Our results also indicate the benefit of using multiple criteria to evaluate suites, as is common practice in studies: while the worst correlation for some subjects is below 0.5, the best is over 0.5 in all but two subjects. Agreement between multiple criteria should increase confidence in a ranking.

Table 5.2:  $\tau_b$  values for Size-varied Selection

# 5.2 Spearman's $\rho$ Rank Correlation

Tables 5.3 and 5.4 show Spearman's  $\rho$  correlation values for all subjects and all criteria we examined, for Coverage-varied Selectionand Size-varied Selection, respectively. The first key observation is that most criteria had positive  $\rho$  values for most subjects. Negative values occurred only with DBB for Coverage-varied Selection. The second key observation is similar to that for Kendall's  $\tau$ : it is clear that BC performs very well, and AIMP seems to perform best of the non-branch criteria (though PCT<sub>BB</sub> has slightly higher means for Coverage-varied Selection).

Table 5.3:  $\rho$  values for Coverage-varied Selection

#### 5.3 Linear Regression

Tables 5.5 and 5.6 show  $R^2$  values for our subjects and criteria. For the primary research question of this paper (the validity of using criteria to predict ranking of mutation scores),  $R^2$  is less relevant than  $\tau_b$  and  $\rho$ , and the validity of relative  $R^2$  values may be compromised by non-linear relationships. However, the overall picture of the correlation between criteria and mutation scores changes from  $\tau_b$  and  $\rho$  to  $R^2$  only in that  $R^2$  suggests that AIMP is often better than BC coverage for quantitative prediction. This confirms the claim that AIMP is the most useful non-BC criterion. We also note that in some cases  $R^2$  for a coverage criterion is too low to suggest it as a valid predictor of mutation score, but Kendall's  $\tau_b$  and Spearman's  $\rho$  show that the criterion nonetheless manages to have a high probability

Table 5.4:  $\rho$  values for Size-varied Selection

to correctly predict rank order of mutation scores.

Test Suite Size: We also examined the importance of suite size as a criterion, because previous work has considered the possibility that coverage criteria are primarily valuable because they force the production of large suites. This is not a major concern for us, because we minimize size as a confounding factor by using a wide range of sizes with numerous suites of each size, and computing  $\tau_b$  and  $\rho$  over all pairs (including many tied in size). We also note that a trend towards comparing only suites that require the same computational effort further reduces the importance of size [36,38,42]. For our subjects, using size alone to predict mutation score is an extremely ineffective predictor, with values of  $\tau_b$ ,  $\rho$ , and  $R^2$  much worse than for other criteria (often < 0.25); we were surprised to even see small negative values

Table 5.5:  $\mathbb{R}^2$  values (mutants~coverage) for Coverage-varied Selection

for  $\tau_b$  and  $\rho$  for some subjects (Tables 5.1 and 5.3). Further, as we show in Tables 5.7 and 5.8 and Tables 5.9 and 5.10, using size as an additional variable in regressions [53] did not change our general results: adding either size or log(size) to coverage values improved  $R^2$  for PCT criteria the most, but BC and AIMP still had higher correlations overall.

### 5.4 Combining Criteria

After observing the high effectiveness of BC, we attempted to exploit it by using BC as a base criterion and breaking ties with stronger criteria. Specifically, we lexicographically compared pairs, e.g.,  $\langle BC, AIMP \rangle$ , for each suite such that BC is the primary criterion

Table 5.6:  $\mathbb{R}^2$  values (mutants~coverage) for Size-varied Selection

to compare suites, and iff two suites have the same BC, then the second criterion (AIMP in the example) is used to predict the mutation score ranking. However, the correlations were almost uniformly worse than for either criterion alone. It is possible that some other weighting of multiple criteria would perform better than any of the studied approaches; however, the complexity of devising such a scheme and measuring multiple criteria does not make this an immediately attractive approach, given that studied criteria are already effective.

Table 5.7:  $\mathbb{R}^2$  values (mutants~coverage+size) for Coverage-varied Selection

#### 5.5 Cost of Measurement

While our key questions are about the predictive power of coverage criteria, we are also interested in the cost of measuring coverage. Table 5.11 shows the average overhead of measuring various criteria using our prototype tools. Our implementation of IMP/AIMP is simple; Ball and Larus [11] provide a much faster precise approach, and the hash-based imprecise approach of Hassan and Andrews would also apply [43]. Our results generally show feasibility for experimental evaluation of test suites, even with a very simple implementation. The key point is that our worst slowdown was slightly over 108X, and computing mutation score can take over 1000X. In some cases, the instrumented code is faster and takes even less time than the original code due to lightweight instrumentation and usual noise in experiments.

Table 5.8:  $\mathbb{R}^2$  values (mutants~coverage+size) for Size-varied Selection

Note that the table does not include numbers for DBB, as the values for this criterion are measured from statement coverage.

## 5.6 Quality of Mutants

Our results depend on the quality of the mutants, i.e., the difficulty of killing them. If all the mutants are easy to kill, a simple coverage criterion may perform unrealistically well. We therefore compare the percentage of tests that kill specific mutants to execution rates for branches. Table 5.12 shows the results; we can see that some mutants, especially for large programs, can be killed by only a small fraction of tests, e.g., only 0.05% of all tests kill the

Table 5.9:  $R^2$  values (mutants~coverage+log(size)) for Coverage-varied Selection

least killed mutant for JFreeChart. It is clear that on average mutants are "harder" than branches for most subjects, with a lower minimum and mean kill/execute rate as well as a higher standard deviation.

# 5.7 Ties for Criteria

A final concern about using criteria to compare test suites in research is the problem of ties—cases when test suites achieve the same coverage. For small subjects and large test pools, researchers often report that branch and statement coverage are highly similar (if not exactly the same) for test techniques that actually have different effectiveness for larger subjects.

Table 5.10:  $\mathbb{R}^2$  values (mutants~coverage+log(size)) for Size-varied Selection

We investigated the likelihood of criteria with smaller number of requirements having larger number of ties. Tables 5.13 and 5.14 show that there are indeed often more than 10% of tied suite pairs for simple subjects with some criteria, but with the exception of LinkedList, very seldom more than 5% with the other, stronger criteria.

## CHAPTER 6

# DISCUSSION

The most surprising result in our study is that BC performs so well. A second somewhat surprising result is that, of non-BC criteria, AIMP performs best and performs much better than the more frequently used IMP, despite the fact that IMP subsumes AIMP. We believe that these two results are related. The ranking of criteria (to predict mutation scores) does not follow the subsumption hierarchy, although one might expect stronger criteria to predict mutation scores better than weaker criteria do. In fact, in many cases, exactly the opposite is true. Our belief is that there is a fundamental tension between strength and predictive power. Consider a criterion C that is weaker than another criterion C'; C' is most likely a better predictor than C for C-adequate suites (e.g., if we have many suites with 100% BC, then we cannot predict varying mutation scores among those suites using BC itself, but we can still use AIMP), but C' is less likely a better predictor than C for C-non-adequate suites (e.g., IMP is a worse predictor than AIMP, but BC is a better predictor than SC).

Viewed differently, we can consider the question: how much information does the coverage value for one criterion provide about the coverage value for another criterion? We realize that a subsumed criterion often (but not always) provides more information about the criterion that subsumes it than the reverse. For example, if a suite has an absolute BC value of k (with each test contributing at least one unique branch), we know that the suite has absolute AIMP, IMP, and PCT values of at least k. However, if we know that a suite has absolute AIMP, IMP, or PCT coverage of k, with each test contributing at least one path or PCT state, the absolute BC may be arbitrarily lower than k. In a sense, the weaker criteria in these cases provide "more" information about a suite, so we can expect them to better predict mutation score. For example, a suite may obtain very high AIMP coverage without executing most code in the program, if the suite takes a huge number of paths through a

single loop with many internal branches; similarly, absolute PCT coverage cannot distinguish between a suite that covers many (irrelevant) states of a small portion of a program and a suite that covers fewer states but executes most of the program. Given the nearly uniform distribution of mutants across a program, suites that do not execute most of the code are likely to have poor mutation scores. In contrast, a high BC value indicates that many easy-to-kill mutants are almost certainly killed. BC thus "warns" if a suite misses many "easy" faults; IMP/AIMP and PCT may not "warn".

The predictive power of BC weakens, however, as suites approach adequacy, when more ties are seen in BC, but mutation scores continue to diverge. The best predictive coverage may be the criterion that minimizes potentially meaningless information without converging too rapidly on 100% coverage. Among our evaluated criteria, AIMP seems to balance information content and avoidance of ties best: it always has a percentage of tied values for suites that is between the very high percentage of ties for BC and the very low percentages for PCT and IMP criteria. IMP had the lowest percentage of ties of all criteria but also proved nearly the least useful for predicting mutation score (Tables 5.13 and 5.14).

The usefulness of AIMP is encouraging. Hassan and Andrews have suggested that one reason def-use and other dataflow coverages have been little used in practice, despite encouraging results in some studies, is the difficulty of implementing the required static analyses [43]. AIMP is usually trivial to add to instrumentation for collecting BC, if a fairly high overhead is acceptable (as done in this paper), and can be much more efficient if needed [11, 57]. Moreover, loop-free paths within a single function are intuitively easy to interpret, and Godefroid's compositional approach to dynamic symbolic execution essentially maximizes AIMP [32]. In future studies evaluating test suites, our results suggest that IMP should be replaced with AIMP.

We believe PCT coverage may be less effective than AIMP because it uses too many predicates. PCT is inspired by abstraction in software model checking, which does not use all in-scope predicates at all points (which leads to a state-space explosion) but instead only uses those relevant to a specification [14,44]. Investigating whether the superior performance of AIMP truly indicates that path-sensitivity is more important than logical-state-space coverage would require a similar selectivity. Unfortunately, the approaches used in model

checking are impractical for testing large programs.

Unlike other coverage criteria, based on our experiments, DBB poorly predicts mutation score. However, note that this holds primarily for data structures for which the number of tests is large as the tests were automatically generated. More precisely, many tests may increase the number of DBBs, but the number of killed mutants may remain constant because most of the mutants for data structures are not hard to kill (Table 5.12). As seen in Table 5.1, this may not be the case with larger programs. Although DBB may not be a good coverage criterion for predicting mutation score, it is effective for fault localization, according to a previous study [12].

As a supporting evidence of our initial example in the introduction (Chapter 1) that used discordant pairs to illustrate difficulty in choosing coverage for evaluating test suites, we measured average number of concordant and discordant pairs for all pairs of criteria. We observe that there are substantial numbers of discordant pairs (Tables 6.1 and 6.2). Also, we observe that the percentage of discordant pairs is similar for Java and C and does not vary substantially among the compared coverage criteria or Size-varied Selection and Coverage-varied Selection.

#### 6.1 Threats to Validity

The primary threat is to external validity: our set of programs and suites, while fairly large by the standards of previous literature, may not be representative of general results. In particular, we examined a larger number of data structures and a smaller number of real-world programs, and our examples were chosen in a partly opportunistic, rather than random, way: we needed subjects with many tests available or easily produced. Our selection of Java data structures, however, at minimum sheds light on the validity of several previous evaluations of testing techniques over these subjects. Construct validity is primarily threatened by ignoring some predicates for PCT because of technical constraints (e.g., we were not able to generate predicates in a class where instrumented methods would exceed the 64KB limit set by the Java classfile specification).

## CHAPTER 7

### RELATED WORK

Many previous studies have investigated the effectiveness of coverage criteria. The contribution of this paper is to perform a large study to address the specific needs of researchers now investigating automated testing techniques: given two test suites, likely non-adequate, what criteria are best for predicting the ability of those suites to kill mutants (and thus, arguably, detect faults)? Are criteria recently adopted by researchers effective for this purpose?

Frankl and Weiss [28] performed an experimental comparison of branch coverage (BC) and def-use coverage, showing that def-use is more effective than BC and that there is stronger correlation between def-use and fault detection than BC and fault detection; their primary conclusions concerned adequate suites, but some experiments included non-adequate suites. Our work targets similar questions but differs in that we compare SC, BC, DBB, IMP, AIMP, and PCT coverages, use larger applications, use a much larger set of tests produced by various testing techniques, use (many) mutants as opposed to (few) real bugs, and extensively explore non-adequate test suites.

Cai and Lyu [13] also investigated the correlation between different coverage criteria—BC, decision coverage, P-use, and C-use—and fault detection, using a linear regression model. Their conclusions are drawn based on experiments on one example, with 426 mutants and 1,200 tests. Different test suites were formed: all tests, tests from a specification, randomly generated tests, tests that cause exceptions, and tests that do not cause exceptions. Their results showed that coverage criteria were only a moderate indicator for fault detection, with large variance for different test suites. Some other studies [27,46] also showed small or inconsistent correlation between coverage criteria and fault detection. Namin and Andrews [53] investigated the correlation between coverage criteria, effectiveness, and size of a test suite. The study showed that both coverage and size are non-linearly correlated with effectiveness.

An additional conclusion was that the best result is achieved if both size and coverage are taken into account. Gupta and Jalote [40] examined the efficiency of coverage criteria using minimal adequate test suites for SC, BC, and predicate coverage (the latter simply being coverage of all atomic predicates from conditionals measured only at the conditionals, not to be confused with PCT). In their results, while predicate coverage was the most effective (correlated to mutation score), BC was the most efficient when suite size was considered. Others (e.g., [3]) used smaller programs and suites than the listed studies, and/or only examined small sets of (seeded) faults. A different kind of study by Wei et al. examined the correlation of BC to fault detection in 14 Eiffel classes, over a period of 2,520 hours of random testing (divided into 6 hour runs) [75]. They found that the correlation between BC and fault detection was very high during the first 10 minutes of testing, when new branches were frequently being covered, but once BC was close to saturated, the correlation became weak, and over 50% of faults were detected during the period between 30 minutes and 6 hours, when BC seldom increased. Their conclusion was that BC is a poor stopping criterion for random testing, and in this setting was not by itself a good measure of suite quality.

Studies investigating related questions (e.g., which criteria are best for prioritizing/minimizing regression suites) are numerous, with results that also vary, though BC has arguably performed fairly well [60]. Harder et al. examined the power of various adequacy criteria, noting the possibility of size as a confounding factor [42]. Another related work is that of Hassan and Andrews [43], which extends previous work [53] to a comparison of BC, defuse coverage, and a novel coverage, called Multi-point Stride Coverage (MPSC), that has resemblances to a generalized version of AIMP. Their results showed that def-use coverage was highly correlated with BC in practice, BC was more correlated with fault detection than other criteria, and MPSC was fairly well correlated with fault detection. Since some MPSC coverages subsume AIMP, we would like to compare the two approaches using rank correlation to see if our findings with respect to strength and predictive power hold here as well. Of all previous studies, we find that only a few [47,53,54,76,76,77] mention Kendall's  $\tau$  or Spearman's  $\rho$  correlations, and those do not provide a comparison of multiple criteria as candidates for use in evaluating suites. For example, Inozemtseva [47] only measures block coverage, and uses machine learning to find a regression involving this measure combined

with suite size, but proposes no guidance as to whether block is the best coverage to measure. In contrast, we use  $\tau_b$  and  $\rho$  to compare criteria, across a variety of suite selection and generation approaches.

One study currently in submission [33] explicitly adapts the evaluation measures for coverage criteria used in this paper and applies them to a different, but related problem. Rather than comparing multiple suites for a single program (the typical research problem), the study addresses the problems of software developers attempting to determine whether a single, existing suite (be it manually manual or automatically generated) for a program is effective. The goal (prediction of mutation scores) is the same, but the purpose is to determine if a single suite would have good mutation score, not to compare suites. Based on data from hundreds of open source Java programs on GitHub, their study finds that statement coverage (vs. block, BC, and a variation of AIMP) best predicts mutation score for both manual suites in the repository and Randoop-generated [58] tests. We speculate that the difference in problem statement (correlation across multiple subjects with a single suite vs. across multiple suites for each subject) drives the difference in results, especially as it presumably results in many fewer ties. In general the results are not radically different than our own—all correlations  $(\tau_b \text{ and } R^2)$  are above 0.65 (and some above 0.9) for all criteria for manually produced suites, though  $\tau_b$  for Randoop suites is relatively low for all criteria (0.48-0.54). The results also confirm our claim that the subsumption hierarchy does not match correlation with mutation scores; in fact, the ranking of criteria in their study is precisely the opposite of the subsumption hierarchy.

Shuler and Zeller [63] propose the idea of *checked coverage* as a measure of oracle, rather than suite, effectiveness. Checked coverage measures coverage over the dynamic slice of statements influencing oracle statements only. They show that for seven open-source projects this approach is better able to detect degradation of oracle quality than even mutation testing. We focus only on traditional suite quality measurement, where the test inputs rather than the oracle alone are the primary target for evaluation.

Baudry et al. [12] introduced the concept of dynamic basic blocks (DBBs) for measuring a test suite's fault localization capability. Our work evaluates the value of DBBs as a coverage metric rather than for fault localization.

Ball [9] introduced the theory behind PCT coverage and showed that PCT subsumes BC and various decision coverages, and is incomparable to path coverage. Although PCT was introduced in 2004 and was used to compare test-generation techniques, it was not extensively evaluated empirically. Our study is the first that implements PCT and empirically investigates the PCT criterion.

Another category of related work includes studies that used some of our criteria for measuring the quality of test suites, which inspired our efforts. Visser et al. [69] were the first to instrument code for measuring an approximation of PCT coverage and compared a number of advanced test generation techniques against random testing using PCT. Because of the lack of tools that can perform instrumentation for PCT, predicates were selected manually. Specifically, not all predicates were selected, the constructed predicates were not instantiated consistently at all points (either blocks or statements), and some predicates were instantiated when they were not in scope. Pacheco et al. [58] used the same approach to PCT to demonstrate the effectiveness of feedback in random test generation. Later, Sharma et al. [65] compared random testing and shape abstraction on the same set of predicates as previous studies, but predicates were instantiated systematically at all basic blocks. An extended version of that instrumentation was used recently [35, 36] to evaluate the effectiveness of a new test generation technique based on reinforcement learning.

The last category of related work includes tools for measuring code coverage. There are many tools available for both Java [19, 26] and C [1] that can measure class, method, statement, branch, and path coverage. Additionally, tools for mutation testing [62] can be placed in this category. Ours is the first tool for systematically measuring Ball's PCT coverage. Because detailed empirical evaluation requires such a tool, we implemented tools, both for Java and C, that can instrument code for measuring PCT. Using our tools, we were able to automatically and systematically instrument reasonably large code bases. The only previous attempt (to our knowledge) to address PCT in practical automated terms was in the FShell system [45], which can perform model checking queries to find paths to satisfy PCT coverage goals in C programs, but relies on being provided a list of relevant predicates, does not distinguish between variables with the same name in different scopes, and does not instrument for runtime collection of coverage data.

## CHAPTER 8

### CONCLUSIONS

This paper considers these questions: (1) for researchers wishing to compare test suites but lacking a statistically significant number of real faults and lacking the computational resources to perform mutation testing, is it useful to compare suites using coverage criteria; if so, (2) which criteria are best at predicting mutation scores? Recent literature has shown that these are critical questions to answer, because publications are increasingly using coverage criteria to compare test suites and techniques. Our results suggest that due to high effectiveness and low overhead, researchers should use branch coverage to compare suites whenever possible, but most evaluated criteria performed well in terms of predicting mutation score for most of our subjects, with only dynamic basic blocks arguably ineffective for many small subjects. A variation of intra-procedural acyclic path coverage performed best of all non-branch coverage criteria, and has desirable simplicity, ease of implementation, and reasonable overhead. Future work should evaluate these and other criteria on a larger set of subject programs and test suites.
